### A1 Data transformation

Proportional cover data were transformed to isometric log-ratio (ilr) coordinates (Egozcue et al., 2003). Let $z_{i,j,t} = [z_{1,i,j,t}, z_{2,i,j,t}, z_{3,i,j,t}]^T$ denote a vector of observed proportional cover of coral ($z_{1,i,j,t}$), algae ($z_{2,i,j,t}$) and other ($z_{3,i,j,t}$) at site $i$, transect $j$, at time $t$ (the $T$ denotes transpose). Then the ilr transformation for our data is given by

$$
\text{ilr}: \mathbb{S}^3 \rightarrow \mathbb{R}^2,
$$

$$
z_{i,j,t} = [z_{1,i,j,t}, z_{2,i,j,t}, z_{3,i,j,t}]^T \mapsto \left[\frac{1}{\sqrt{2}} \log \left( \frac{z_{2,i,j,t}}{z_{1,i,j,t}} \right), \frac{2}{\sqrt{6}} \log \left( \frac{z_{3,i,j,t}}{\sqrt{z_{1,i,j,t} z_{2,i,j,t}}} \right) \right]^T,
$$

(A.1)

where $\mathbb{S}^3$ denotes the open 2-simplex in which three-part compositions lie. The first element of the transformed composition is proportional to the natural log of the ratio of algae to coral, and the second element is proportional to the natural log of the ratio of other to the geometric mean of algae and coral. The transformation can be thought of as stretching out the open 2-simplex (Figure A2(a)) so that it covers the whole of the real plane (Figure A2(b)).
As the domain of the transformation is the open simplex, which does not include compositions
with zero parts, any observed zeros were replaced by half the smallest non-zero value recorded
(0.0008) before transformation, and the other components rescaled accordingly. This is the simple
replacement strategy described in Martín-Fernández et al. (2003), although more sophisticated
approaches are possible. We denote the resulting transformed observations by
\[ y_{i,j,t} = [y_{1,i,j,t}, y_{2,i,j,t}]^T. \]

### A2 The model

For convenience, we reproduce the full model equations here:

\[
\begin{align*}
    x_{i,t+1} &= a + \alpha_i + B x_{i,t} + \varepsilon_{i,t}, \\
    \alpha_i &\sim \mathcal{N}(0, Z), \\
    \varepsilon_{i,t} &\sim \mathcal{N}(0, \Sigma), \\
    y_{i,j,t} &\sim t_2(x_{i,t}, H, v),
\end{align*}
\]

(A.2)

where \( x_{i,t} \) is the true transformed composition at site \( i \), time \( t \), \( a \) is a vector of among-site mean
proportional changes evaluated at \( x_{i,t} = 0 \), \( \alpha_i \) represents the amount by which these proportional
changes for the \( i \)th site differ from the among-site mean, the \( 2 \times 2 \) matrix \( B \) represents the effects
of \( x_{i,t} \) on the proportional changes, \( \varepsilon_{i,t} \) represents random temporal variation,

\[
Z = \begin{bmatrix}
    \zeta_{11} & \zeta_{12} \\
    \zeta_{21} & \zeta_{22}
\end{bmatrix}
\]

is the covariance matrix of the among-site term \( \alpha_i \) (note that throughout, a diagonal element such
as \( \zeta_{ii} \) of a covariance matrix represent the variance of the \( i \)th variable),

\[
\Sigma = \begin{bmatrix}
    \sigma_{11} & \sigma_{12} \\
    \sigma_{21} & \sigma_{22}
\end{bmatrix}
\]
is the covariance matrix of the temporal variation, \( y_{i,j,t} \) is the observed log-ratio transformed cover in the \( j \)th transect of site \( i \) at time \( t \), 

\[
H = \begin{bmatrix}
\eta_{11} & \eta_{12} \\
\eta_{21} & \eta_{22}
\end{bmatrix}
\]

is the scale matrix of the bivariate \( t \) distribution of the \( y_{i,j,t} \), and \( \nu \) is the corresponding degrees of freedom.

### A3 Describing measurement error and small-scale temporal variability

We initially considered using a bivariate normal distribution to describe the variability of observed transformed composition \( y_{i,j,t} \) around true composition \( x_{i,t} \), but preliminary analyses showed that a heavier-tailed distribution was needed. We therefore used the bivariate \( t \) distribution with location vector \( x_{i,t} \), scale matrix \( H \) and degrees of freedom \( \nu \), which for \( \nu > 2 \) has covariance matrix \( \nu H / (\nu - 2) \) (Lange et al., 1989). Support for the choice of the \( t \) over the normal distribution was provided by expected predictive accuracy based on leave-one-out cross-validation (Vehtari et al., 2015), which was much higher for the bivariate \( t \) model than for the bivariate normal model (difference in leave-one-out cross-validation score 527, standard error 48).

### A4 Visualizing model parameters

The effects of reef composition on short-term dynamics are most easily visualized by the back transformation from ilr coordinates to the simplex of the columns of the matrix \( A = B - I_2 \), where \( I_k \) denotes the \( k \times k \) identity matrix. The matrix \( A \) describes effects of transformed reef composition on year-to-year changes in transformed reef composition (Cooper et al., 2015). This is a better visualization than the back transformation of \( B \), because in the random walk case
(where there are no interesting composition effects), $A = 0_2$ (the $2 \times 2$ matrix of zeros), and each column of the back-transformation of $A$ represents a point at the origin of the simplex. In contrast, in the random walk case, each column of the back transformation of $B = I_2$ represents a point at a different location in the simplex. The first column $a_1$ of $A$ represents the effect of a unit increase in the first component of reef composition (proportional to log(algae/coral)) on year-to-year change in reef composition. For example, if the back-transformation of $a_1$ lies to the left of the centre of the simplex (the origin, with equal proportions of coral, algae and other), but on the line of equal relative abundances of coral and other (the 1:1 coral-other isoproportion line), it indicates that high algal cover relative to coral tends to result in a decrease in algae relative to coral in the following year. Similarly, the second column $a_2$ of $A$ represents the effect of a unit increase in the second component of reef composition (proportional to log(other/geometric mean(algae,coral))) on year-to-year change in reef composition.

### A5 Parameter estimation

Code for all analyses is available at [https://www.liverpool.ac.uk/~matts/kenya.zip](https://www.liverpool.ac.uk/~matts/kenya.zip).

#### A5.1 Priors

For $Z$ and $\Sigma$, our priors were based on data from the Great Barrier Reef (Cooper et al., 2015). We inspected the sample covariance matrices for ilr-transformed year-to-year changes in composition, and among-site variation in mean composition, on 55 sites in the Great Barrier Reef, where observation error is thought to be fairly small (Cooper et al., 2015). We chose inverse Wishart priors (Gelman et al., 2003, p. 574) with 4 degrees of freedom (the smallest value for which the prior mean exists, giving a fairly uninformative prior). We chose identity scale matrices, because ellipses of unit Mahalanobis distance around the origin for the mean of this prior almost enclosed corresponding ellipses for the sample covariance matrices of both year-to-year changes and among-site mean composition, and strong correlations among
transformed components are neither assumed nor ruled out. Thus, this seems a plausible prior for $\Sigma$ and $Z$. In the absence of strong prior information, we used the same prior for $H$.

For the degrees of freedom of measurement error, $\nu$, we assumed a $U(2, 30)$ distribution. The lower bound was dictated by the requirement that $\nu > 2$ for the covariance to exist, and the upper bound was chosen to be large enough that the resulting measurement error distribution was able to approach a multivariate normal if necessary. In practice, the posterior distribution of $\nu$ did not pile up against either of these bounds, indicating that the precise choice of prior was unlikely to matter.

We chose vague priors for the other parameters. We assumed independent $\mathcal{N}(0, 10)$ priors on each element of $x_{i,0}$ for each site $i$ (where the subscript 0 denotes the first time point at which the site was observed). For each element of $a$ and $B$, we assumed independent $\mathcal{N}(0, 100)$ priors.

A5.2 Monte Carlo simulation

We ran four Monte Carlo chains in parallel for 5000 iterations each, after a 5000-iteration warmup period. This took approximately two hours on a 64-bit Ubuntu 12.04 system with 4 3.2 GHz Intel Xeon cores and 16 GiB RAM. The potential scale reduction statistic, which takes the value 1 if all chains have converged to a common distribution, was 1.00 to two decimal places for all parameters, consistent with satisfactory convergence (Stan Development Team, 2015, pp. 414-415). Effective sample sizes, which measure the size of the sample from the posterior distribution after accounting for autocorrelation in the Monte Carlo chains (Stan Development Team, 2015, pp. 417-419), were at least 2839 for all parameters (most were much larger, with first quartile 12430 and median 17490). Inspection of trace plots did not reveal any obvious problems with sampling. In addition, we evaluated the model’s performance in estimating known parameters. We generated 100 simulated data sets with identical structure to the real data, using posterior mean estimates for each parameter. We sampled the $\alpha_i$, $\varepsilon_{i,t}$ and $y_{i,j,t}$ from distributions defined by Equation A.2, and set the initial true transformed compositions at a given site to the sample means from all years and transects on that site in the real data. The estimates were reasonably close to the true values, and lay within the 95% HPD intervals in 89-99 out of 100
cases (Figure A3). Thus, while estimating state-space models from ecological time series data can be challenging (Auger-Méthé et al., 2015), performance appears adequate in this case, perhaps because we have many replicate transects from which to estimate measurement error and small-scale spatial variability, and most parameters are estimated using data across many sites.

A5.3 Model checking

We examined plots of Bayesian residuals (Gelman et al., 2003, p. 170) against predicted values of the two components of transformed reef composition. For the $k$th Monte Carlo iteration, the Bayesian residual for the $j$th transect on the $i$th site at time $t$ is $y_{i,j,t} - x_{i,t} | \theta_k$, where $\theta_k$ denotes the estimated parameters in the $k$th iteration. If the model is performing well, there should be no obvious relationship between residuals and fitted values. We checked 16 randomly-chosen iterations, which did not reveal any major cause for concern (Figures A4, A5). However, no residuals for component 1 fell below an obvious diagonal line (Figure A4), which results from the treatment of observed zeros. Given the simple replacement strategy for zeros described in Section A1 and the definition of component 1 of the transformed composition in Equation A.1,

\[
y_{1,i,j,t} = \frac{1}{\sqrt{2}} \log \left( \frac{z_{2,i,j,t}}{z_{1,i,j,t}} \right) \geq \frac{1}{\sqrt{2}} \log \left( \frac{0.0008}{0.9984} \right) = -5.0216.
\]

Thus the Bayesian residual for component 1 is constrained by

\[
y_{1,i,j,t} - x_{1,i,t} | \theta_k \geq -5.0216 - x_{1,i,t} | \theta_k,
\]

the orange line on Figure A4. Thus the assumption of a multivariate $t$ distribution for individual transect deviations from true values (Equation A.2) cannot hold exactly. It might in future be worth attempting to develop a more mechanistic model of the process generating observed zeros, but we do not attempt this here because the majority of data are unaffected. Although a similar constraint exists on component 2, it did not appear to be important in practice, because there is no
obvious diagonal line of residuals on Figure A5.

Inspection of quantile-quantile plots and histograms of estimated skewness and kurtosis for 16 iterations did not indicate any major problems with the assumptions of multivariate normal distributions with zero mean, covariance matrices $Z$ and $\Sigma$ respectively for $\alpha$ and $\varepsilon$, and a multivariate $t$ distribution with zero location vector, scale matrix $H$, for Bayesian residuals. Quantile-quantile plots used the natural log of a squared Mahalanobis-like distance/2 against natural log of quantiles of $\chi^2(2)$ for multivariate normal distributions, or against natural log of quantiles of $F(2, \nu)$ for multivariate $t$ distributions (modified from Lange et al., 1989). We did not transform to asymptotically standard normal deviates because the degrees of freedom for the $t$ distribution were small. We found it helpful to log transform both axes, particularly for the multivariate $t$ distribution, for which some observations may have very large squared Mahalanobis-like distance. We obtained the $p$-values for several tests of multivariate normality of $\alpha$ and $\varepsilon$: Royston’s $H$ (Royston, 1982), Henze-Zirkler’s test (Henze and Zirkler, 1990), and Mardia’s skewness and kurtosis (Mardia, 1970) using the MVN package in R (Korkmaz et al., 2014). There were more small $p$-values than expected (the distribution of $p$-values should be approximately uniform in the interval (0,1) if the data are normal) but that often is the case for very large samples, and does not indicate a major cause for concern.

**A6 Long-term behaviour**

Iterating Equation A.2 from a fixed initial transformed composition $x_{i,0}$,

$$x_{i,t} = \sum_{j=0}^{t-1} B^j a + \sum_{j=0}^{t-1} B^j \alpha_i + B^t x_0 + \sum_{j=0}^{t-1} B^j \varepsilon_{i,t-1-j} \quad (A.3)$$

If all the eigenvalues of $B$ lie inside the unit circle in the complex plane, the system will converge to a stationary distribution as $t \rightarrow \infty$ (e.g. Lütkepohl, 1993, p. 10). If the eigenvalues of $B$ are complex, they will form a complex conjugate pair $\lambda = re^{\pm i\theta}$ (where $r$ is the magnitude and $\theta$ is the argument), and there will be oscillations with period $2\pi/\theta$, whose amplitudes will change by
a factor of $r$ each year (e.g. Otto and Day, 2007, p. 355).

The first term in Equation A.3 is deterministic, and converges to

$$\mu^* = (I_2 - B)^{-1}a$$  \hspace{1cm} (A.4)

(e.g. Lütkepohl, 1993, p. 10), which represents the among-site mean of stationary mean transformed composition. The third term is also deterministic, and converges to 0, so that initial conditions are forgotten.

The second term, representing among-site variation, has mean vector 0 by definition, and the covariance matrix of its limit is

$$Z^* = V \left[ (I_2 - B)^{-1} \alpha_i \right]$$

$$= (I_2 - B)^{-1} V \left[ \alpha_i \right] \left( (I_2 - B)^{-1} \right)^T$$

$$= (I_2 - B)^{-1} Z \left( (I_2 - B)^{-1} \right)^T, \hspace{1cm} (A.5)$$

since $(I_2 - B)^{-1}$ is a constant matrix and $\alpha_i$ is a random vector. The covariance matrix $Z^*$ represents the among-site variation in stationary mean transformed composition.

The fourth term represents the long-term effects of temporal variability. It has mean vector 0 by definition, and it can be shown that it has covariance matrix

$$\Sigma^* = \text{vec}^{-1} \left( (I_4 - B \otimes B)^{-1} \text{vec} (\Sigma) \right)$$  \hspace{1cm} (A.6)

(e.g. Lütkepohl, 1993, p. 22), where the vec operator stacks the columns of a matrix, vec$^{-1}$ unstacks them, and $\otimes$ is the Kronecker product. The covariance matrix $\Sigma^*$ can be interpreted as the stationary covariance of transformed reef composition, conditional on the value of $\alpha_i$. Since among-site variation and temporal variation were assumed independent, the unconditional stationary covariance is $\Sigma^* + Z^*$. Both the conditional and unconditional stationary distributions
are multivariate normal, since both $\varepsilon_{i,t}$ and $\alpha_i$ were assumed multivariate normal. Thus the
stationary distribution for a randomly-chosen site is the multivariate normal vector

$$x^* \sim \mathcal{N}(\mu^*, \Sigma^* + Z^*). \tag{A.7}$$

To find the long-term behaviour for a given site $i$, we condition on the value of $\alpha_i$. Thus Equation
A.4 is replaced by

$$\mu^*_i = (I_2 - B)^{-1}(a + \alpha_i),$$

and the stationary distribution is

$$x^*_i \sim \mathcal{N}(\mu^*_i, \Sigma^*).$$

### A7 How important is among-site variability?

From Equation A.7, the covariance matrix $\Sigma^* + Z^*$ of the stationary distribution for a
randomly-chosen site contains contributions from both among- and within-site variability. To
quantify the contributions from these two sources, we will use a statistic based on a ratio of
generalized variances.

The generalized variance of a multivariate distribution is defined as the determinant of the
 covariance matrix (Wilks, 1932; Johnson and Wichern, 2007, section 3.4). In the specific case of a
multivariate normal distribution, the generalized variance may be interpreted in terms of *ellipsoids
of concentration*, defined as follows. Suppose a random vector $\mathbf{W}$ is distributed according to a
$p$-dimensional normal distribution with mean vector $\mu$ and covariance matrix $\mathbf{V}$. Then for any
constant $k \geq 0$, the set $E_k = \left\{ \mathbf{w} : (\mathbf{w} - \mu)^T \mathbf{V}^{-1} (\mathbf{w} - \mu) = k \right\}$ consists of points $\mathbf{w}$ of constant
probability density. In $p = 2$ dimensions, $E_k$ is an ellipse, and may be referred to as a probability
density contour. In $p > 2$ dimensions $E_k$ is known as an ellipsoid of concentration of $\mathbf{V}$ about $\mu$. 

9
Taking $k = 1$, the set $E_1$ is known as the unit ellipsoid of concentration. The volume within the unit ellipsoid $E_1$ may be used as a measure of the dispersion of the distribution, and is equal to $S_p \sqrt{|V|}$, where $S_p$ is the volume of the $p$-dimensional sphere of radius 1. In the light of the above interpretation, we chose to measure the contribution of within-site variability to total variability using the quantity

$$\rho = \left( \frac{|\Sigma^*|}{|\Sigma^* + Z^*|} \right)^{1/2},$$  \hspace{1cm} (A.8)

which is the ratio of volumes of two unit ellipsoids of concentration, the numerator corresponding to the stationary distribution in the absence of among-site variation, and the denominator to the full stationary distribution of transformed reef composition in the region. This ratio is undefined if $\Sigma^* + Z^*$ is not of full rank, but this does not occur in our application. From Minkowski’s theorem (Mirsky, 1955, section 13.5) it follows that $|\Sigma^*| + |Z^*| \leq |\Sigma^* + Z^*|$, so that $0 \leq \rho \leq 1$. However, in general $|\Sigma^*| + |Z^*| \neq |\Sigma^* + Z^*|$, so that $\rho$ cannot be simply interpreted as the proportion of total variability explained by within-site variation. Nevertheless, $\rho$ provides an indication of how much of the total variability would remain if all among-site variability was removed. Furthermore, $\rho^2$ is analogous to Wilks’ Lambda (Wilks, 1932; Kenward, 1979), a likelihood-ratio test statistic often used in multivariate analysis of variance.

**A8 Probability of low coral cover**

For a given site $i$, the long-term probability $q_{\kappa,i}$ of coral cover less than or equal to $\kappa$ is the integral of the multivariate normal stationary density for the site over the shaded area in Figure A36 (for $\kappa = 0.1$). This can be written as

$$q_{\kappa,i} = 1 - \int_{-\infty}^u P(X_2 \leq \gamma | X_1 = x_1) f_{X_1}(x_1) \, dx_1,$$  \hspace{1cm} (A.9)
where, using Equations A.1 and the constraint that the untransformed components of benthic
composition must sum to 1,

\[ u = \frac{1}{\sqrt{2}} \log \left( \frac{1}{\kappa} - 1 \right) \]

is the largest value of the first ilr component \( x_1 \) for which it is possible to have coral cover less
than or equal to \( \kappa \),

\[ \gamma = \frac{2}{\sqrt{6}} \log \left( \frac{1 - \kappa \left( 1 + e^{\sqrt{2} x_1} \right)}{\kappa \sqrt{e^{\sqrt{2} x_1}}} \right) \]

is the value of the second ilr component \( x_2 \) for which coral cover is equal to \( \kappa \), given the value of
\( x_1 \), \( P(X_2 \leq \gamma | X_1 = x_1) \) is the conditional marginal cumulative distribution of \( x_2 \), given the value of
\( x_1 \), and \( f_{X_1}(x_1) \) is the unconditional marginal density of the first ilr component \( x_1 \).

Since

\[ \mathbf{X} = [X_1, X_2]^T \sim \mathcal{N}(\mu^*_i, \Sigma^*_i), \]

the unconditional marginal distribution of \( x_1 \) is

\[ \mathcal{N}(\mu^*_{1,i}, \sqrt{\sigma^*_{11,i}}), \quad (A.10) \]

and the conditional marginal distribution of \( x_2 \) given \( x_1 \) is

\[ \mathcal{N} \left( \mu^*_{2,i} + \frac{\sigma^*_{21,i}}{\sigma^*_{11,i}} (x_1 - \mu^*_{1,i}), \sigma^*_{22,i} - \frac{(\sigma^*_{21,i})^2}{\sigma^*_{11,i}} \right), \quad (A.11) \]

(Gelman et al., 2003, p. 579). Then the integral in Equation A.9 can be approximated numerically
using the \texttt{integrate()} function in R (R Core Team, 2015), which is based on routines in
Piessens et al. (1983). The same approach can be used for \( q_\kappa \) for a randomly-chosen site,
replacing the elements of \( \mu^*_i \) and \( \Sigma^*_i \) in Equations A.10 and A.11 with the corresponding
elements of $\mu^*$ and $\Sigma^*$.

A9  Spline correlograms for spatial pattern in probability of low coral cover

We calculated a spline correlogram (Bjørnstad and Falck, 2001) for each set of $q_{0.1,i}$ in the 20000 Monte Carlo iterations, using the `spline.correlog()` function in the R package ncf version 1.15. We constructed a 95% highest-density envelope (Hyndman, 1996) for the resulting set of correlograms using the R package hdrcde version 3.1.

A10 Which model parameters have the largest effects on the probability of low coral cover?

For a given threshold $\kappa$, we can calculate (by numerical integration) the probability

$$q_\kappa = P(\text{coral cover} \leq \kappa),$$

for a composition drawn from the stationary distribution on a site chosen at random from the region. The probability $q_\kappa$ is a function of 12 parameters: all four elements of $B$; both elements of $a$; elements $\sigma_{11}$, $\sigma_{21}$ and $\sigma_{22}$ of $\Sigma$; and elements $\zeta_{11}$, $\zeta_{21}$ and $\zeta_{22}$ of $Z$. Note that because $\Sigma$ and $Z$ are covariance matrices, they must be symmetric, and so $\sigma_{12}$ and $\zeta_{12}$ are not free parameters. These 12 parameters can be thought of as the coordinates of a point in $\mathbb{R}^{12}$. The steepest reduction in $q_\kappa$ as we move through $\mathbb{R}^{12}$ is achieved by moving in the direction of $-\nabla q_\kappa$, where $\nabla q_\kappa$ is the gradient vector $[\partial q_\kappa/\partial b_{11}, \ldots, \partial q_\kappa/\partial \zeta_{22}]^T$ (Riley et al., 2002, p. 355).

To understand the effects of each parameter, note that the probability $q_\kappa$ depends on these parameters only through $\mu^*$, $\Sigma^*$ and $Z^*$. Thus, for any parameter matrix $\Theta$, using the chain rule for matrix derivatives,

$$Dq_\kappa(\Theta) = Dq_\kappa(\mu^*)D\mu^*(\Theta) + Dq_\kappa(\Sigma^*)D\Sigma^*(\Theta) + Dq_\kappa(Z^*)DZ^*(\Theta),$$
where $D \mathbf{E}(\mathbf{X})$ denotes the matrix derivative of $\mathbf{E}$ with respect to $\mathbf{X}$ (Magnus and Neudecker, 2007, p. 108). This allows us to break up the effects of a parameter into its effects via the stationary mean and stationary within- and among-site covariances. In each term, the first factor $(Dq_{\kappa}(\mu^*), Dq_{\kappa}(\Sigma^*)$ or $D\Sigma^*(\Theta))$ can only be found numerically. The non-zero second factors are

\begin{align*}
D\mu^*(\mathbf{B}) &= (\mathbf{a}^T \otimes \mathbf{I}_2) \left[ ((\mathbf{I}_2 - \mathbf{B})^{-1})^T \otimes (\mathbf{I}_2 - \mathbf{B})^{-1} \right], \\
D\Sigma^*(\mathbf{B}) &= \mathbf{F} \left[ (\text{vec}\Sigma)^T \otimes \mathbf{I}_4 \right] \left[ ((\mathbf{I}_4 - \mathbf{B} \otimes \mathbf{B})^{-1})^T \otimes (\mathbf{I}_4 - \mathbf{B} \otimes \mathbf{B})^{-1} \right] \\
& \quad \left( \mathbf{I}_2 \otimes \mathbf{K}_4 \otimes \mathbf{I}_2 \right) \left( \mathbf{I}_4 \otimes \text{vec}\mathbf{B} + \text{vec}\mathbf{B} \otimes \mathbf{I}_4 \right), \\
D\mathbf{Z}^*(\mathbf{B}) &= \mathbf{F} \left[ (\text{vec}\mathbf{Z})^T \otimes \mathbf{I}_4 \right] \left[ (\mathbf{I}_2 \otimes \mathbf{K}_4 \otimes \mathbf{I}_2) \left( \mathbf{I}_4 \otimes \text{vec}(\mathbf{I}_2 - \mathbf{B})^{-1} + \text{vec}(\mathbf{I}_2 - \mathbf{B})^{-1} \otimes \mathbf{I}_4 \right) \\
& \quad \left[ ((\mathbf{I}_2 - \mathbf{B})^{-1})^T \otimes (\mathbf{I}_2 - \mathbf{B})^{-1} \right], \\
D\mu^*(\mathbf{a}) &= (\mathbf{I}_2 - \mathbf{B})^{-1}, \\
D\Sigma^*(\Sigma) &= \mathbf{F}(\mathbf{I}_4 - \mathbf{B} \otimes \mathbf{B})^{-1} \mathbf{G}, \\
D\mathbf{Z}^*(\mathbf{Z}) &= \mathbf{F} \left[ (\mathbf{I}_2 - \mathbf{B})^{-1} \otimes (\mathbf{I}_2 - \mathbf{B})^{-1} \right] \mathbf{G},
\end{align*}

where $\mathbf{K}_4$ is the $4 \times 4$ commutation matrix (Magnus and Neudecker, 2007, p. 54),

\[
\mathbf{F} = \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix},
\]

and

\[
\mathbf{G} = \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix}.
\]
The derivatives in section A10 measure the rate of change of the probability of low coral cover, $q_\kappa$, with respect to absolute changes in parameters. However, because parameters may differ in magnitude, it is also of interest to measure the rate of relative change of $q_\kappa$ with respect to relative change in each parameter, in other words the elasticity of $q_\kappa$ with respect to the parameter. The usual definition of the elasticity $\text{El}_\theta(q_\kappa(\theta))$ of $q_\kappa$ with respect to a parameter $\theta$ is

\[
\text{El}_\theta(q_\kappa(\theta)) = \lim_{\Delta \theta \to 0} \frac{(\Delta q_\kappa)/q_\kappa(\theta)}{(\Delta \theta)/\theta} = \lim_{\Delta \theta \to 0} \frac{\theta}{q_\kappa(\theta)} \frac{q_\kappa(\theta + \Delta \theta) - q_\kappa(\theta)}{\Delta \theta} = \frac{\theta}{q_\kappa(\theta) q_\kappa'(\theta)}.
\]

(Nievergelt, 1983) for $\theta \neq 0$ (typically, $\theta > 0$) and $q_\kappa(\theta) \neq 0$. We need to slightly change the usual definition because in our model there are three parameters ($b_{12}, b_{21}$ and $\zeta_{12}$) for which both positive and negative values occur in the sample from the posterior. First, although the first line of Equation A.13 is not defined at $\theta = 0$, the continuous function on the second line is defined (and has the value 0) at $\theta = 0$, agrees with the first line at all points other than $\theta = 0$, and tends to 0 as $\theta \to 0$. It therefore fills the gap in a natural way. Second, we would like the elasticity to be positive when the derivative of $q_\kappa$ with respect to $\theta$ is positive, even when $\theta$ is negative. We therefore calculated elasticities as

\[
\text{El}_\theta(q_\kappa(\theta)) = \frac{|\theta|}{q_\kappa(\theta) q_\kappa'(\theta)}.
\]
How informative is a snapshot about long-term site properties?

Denote the true state of a randomly-chosen site at a given time by $x$, and the corresponding stationary mean for that site by $\mu^*$. Under the model of Equation A.2, $\mu^*$ has covariance matrix $Z^*$ (Equation A.5). Write the true state as $x = \mu^* + \Delta$, where $\Delta$ is the deviation from the stationary mean, which has covariance matrix $\Sigma^*$ (Equation A.6). The correlation $\rho_k$ between the $k$th component $x_k$ of $x$ and the corresponding component $\mu_{k}^*$ of $\mu^*$ is an obvious way to measure how informative the snapshot will be for this component. This is

$$\rho_k = \frac{\text{cov}(\mu_{k}^* + \Delta_k, \mu_{k}^*)}{\sqrt{V[\mu_{k}^* + \Delta_k]V[\mu_{k}^*]}} = \frac{V[\mu_{k}^*] + \text{cov}(\mu_{k}^*, \Delta_k)}{\sqrt{V[\mu_{k}^*] + V[\Delta_k]V[\mu_{k}^*]}} = \frac{V[\mu_{k}^*]}{\sqrt{(V[\mu_{k}^*] + V[\Delta_k])V[\mu_{k}^*]}} \quad \text{(because } \alpha \text{ and } \varepsilon \text{ assumed independent) \}

$$

$$= \left(\frac{\zeta_{kk}^*}{\zeta_{kk}^* + \sigma_{kk}^*}\right)^{1/2},$$

where $\zeta_{kk}^*$ is the $k$th diagonal element of $Z^*$, and $\sigma_{kk}^*$ is the $k$th diagonal element of $\Sigma^*$. If $\rho_k$ is far from zero, a snapshot will be a reliable guide to the long-term value of the $k$th component of transformed reef composition. On the other hand, if $\rho_k$ is close to zero, a snapshot will be unreliable. Thus $\rho_k$ measures the extent to which conservation and management decisions could be based on observations at a single time point. We computed both $\rho_1$ which tells us how much we could learn about the log of the ratio of algae to coral and $\rho_2$, which tells us how much we could learn about the log of the ratio of other to the geometric mean of coral and algae.

Dynamics

Consistent with the patterns suggesting negative feedbacks that will tend to maintain fairly stable reef composition, every set of sampled parameters led to a stationary distribution (Figure A37: all
sampled eigenvalues of $B$ fell inside the unit circle in the complex plane, with maximum magnitude 0.84). In 27% of iterations, there was evidence for oscillations on the approach to the stationary distribution, because the eigenvalues were complex. In such cases, the oscillations had a long period (posterior mean 113 years, 95% HPD interval $(21, 284)$ years), but their amplitude more than halved within three years because the magnitudes of the eigenvalues involved were small (original posterior mean magnitude of complex eigenvalues 0.59, 95% credible interval $(0.51, 0.67)$, cubed posterior mean magnitude 0.21, 95% HPD interval $(0.13, 0.30)$). The distribution of eigenvalues was very different from that of the Great Barrier Reef (Cooper et al., 2015, Appendix A.10), where the largest eigenvalue lay close to the point beyond which the stationary distribution would not exist (bootstrap mean magnitude 0.95), and there was no evidence for oscillations (no bootstrap replicates had complex eigenvalues). However, a different estimation method was used in Cooper et al. (2015), so the eigenvalues may not be directly comparable.

### A14 Probability of low coral cover: signs of derivatives

Here, we explain the signs of the derivatives of the probability of low coral cover with respect to each parameter. We concentrate on coral cover threshold 0.1. The overall stationary mean $\mu^*$ lies in the region where coral cover is greater than 0.1 for all iterations (Figure A36, black circle, shows a point estimate for $\mu^*$, based on the stationary means of $a$ and $B$). The shaded region of Figure A36 has coral cover $\leq 0.1$. Because of the shape of the boundary of the shaded region, either increasing $\mu_1^*$ (increasing the ratio of algae to coral) or increasing $\mu_2^*$ (increasing the ratio of other to the geometric mean of coral and algae) will move the stationary mean closer to this region. Also, since the stationary mean lies outside the region of interest, increasing the variability in the stationary distribution by increasing the elements of $\Sigma^*$ or $Z^*$ will increase the probability of falling in the region of interest. Hence the derivatives of $q_{0.1}$ with respect to $\mu^*$, $\Sigma^*$, $Z^*$ contain only positive elements.
It is then intuitively obvious that the derivatives of $q_{0.1}$ with respect to $\Sigma$ and $Z$ will contain only positive elements. Increasing the amount of year-to-year temporal variability or among-site variability will increase the variability in the stationary distribution, and hence the long-term probability of coral cover less than or equal to 0.1.

The signs of the derivatives of $q_{0.1}$ with respect to $a$ are also easy to understand. The components $a_1, a_2$ represent the rates of increase of $x_1$ and $x_2$ respectively, so we would expect that increasing either of them will increase the corresponding component of the stationary mean. Thus the derivatives of $\mu^*$ with respect to $a$ will be positive, and from Figure A36, increasing either component of $\mu^*$ will increase the probability of coral cover $\leq 0.1$.

The derivatives of $q_{0.1}$ with respect to $B$ are a little harder to understand. They are (predominantly) negative with respect to $b_{11}$ and $b_{21}$, but positive with respect to $b_{12}$ and $b_{22}$. Since $B$ affects both the stationary mean (Equation A.4) and the stationary covariance, which is the sum of $\Sigma^*$ (Equation A.6) and $Z^*$ (Equation A.5), all of these effects could be important. However, in 93% of iterations,

$$|Dq_{0.1}(\mu^*)D\mu^*(B)| \succ |Dq_{0.1}(\Sigma^*)D\Sigma^*(B) + Dq_{0.1}(Z^*)DZ^*(B)|,$$

where $\succ$ is an elementwise inequality, and $|D|$ indicates the elementwise magnitude, such that for two matrices $D$ and $E$ with the same dimensions, $|D| \succ |E|$ if and only if the magnitude of every $d_{ij}$ is greater than the magnitude of the corresponding $e_{ij}$. In other words, in almost all iterations, the sign of the effect of $B$ on $q_{0.1}$ via $\mu^*$ determines the sign of the overall effect of $B$ on $q_{0.1}$. We therefore concentrate on understanding how $B$ affects $\mu^*$.

To understand the signs of the effects of $b_{11}$ and $b_{22}$ on $\mu^*$, consider the one-dimensional deterministic analogue

$$x_{t+1} = a + bx_t.$$

Iterating this gives
\[ x_t = a \left( 1 + b + b^2 + \ldots + b^{t-1} \right) + b^t x_0. \]

For \( 0 < b < 1 \), the term \( b^t x_0 \to 0 \) as \( t \to \infty \). Then the derivative of \( x_\infty \) with respect to \( b \) has the same sign as \( a \). In our system, \( a_1 < 0 \) and \( a_2 > 0 \), so we expect the signs of derivatives of \( \mu^* \) with respect to \( b_{11} \) to be negative, and the signs of derivatives of \( \mu^* \) with respect to \( b_{22} \) to be positive.

To understand the signs of the effects of \( b_{12} \) and \( b_{21} \) on \( \mu^* \), recall that \( b_{12} \) is the effect of component 2 (which typically takes positive values) on component 1, and \( b_{21} \) is the effect of component 1 (which typically takes negative values) on component 2. If, as in our system, \( b_{12} \) and \( b_{21} \) are both positive, and the system is linear, we would expect that the signs of their effects on \( \mu^* \) will be the same as the signs of components 2 and 1 respectively.

Then, by the graphical argument above (Figure A36), we expect the signs of the derivatives of \( q_{0.1} \) with respect to \( b_{11} \), \( b_{21} \), \( b_{12} \) and \( b_{22} \) to be \(-,-,+,+\) respectively.

### A15 Probability of low coral cover: rank order, other thresholds and elasticities

For threshold 0.05, the signs of the effects of \( b_{11} \) and \( b_{21} \) were not clearly negative. The four most important parameters were (in descending order: Figure A41) \( \zeta_{21} \), \( \zeta_{22} \), \( b_{22} \) and \( b_{12} \) (the same four as for threshold 0.1, but in a different order). For threshold 0.2, the signs were as for threshold 0.1, but the four most important parameters were (in descending order) \( b_{22} \), \( b_{21} \), \( b_{12} \) and \( \zeta_{21} \) (with \( \zeta_{22} \) now in fifth place: Figure A43). Thus, while the details depend to some extent on the threshold, the overall conclusion that both internal dynamics and among-site variability are the most important factors affecting the probability of low coral cover is robust.

The effects of within-site temporal variability on the probability of low coral cover were always relatively unimportant (threshold 0.1, Figure A39, three of the last four positions in the ranked list; threshold 0.05, Figure A41, three of the last five positions; threshold 0.20, Figure A43, last
three positions).

For elasticities, the four most important parameters (in descending order) for threshold 0.1 were $b_{22}$, $a_1$, $a_2$ and $\zeta_{11}$ (Figure A44). The rank order of importance was similar for thresholds 0.05 (four most important parameters $b_{22}$, $a_1$, $\zeta_{11}$ and $a_2$, Figure A45) and 0.2 (four most important parameters $b_{22}$, $a_1$, $a_2$ and $\beta_{11}$, Figure A46). In all cases, elasticities were higher for elements of the among-site covariance matrix $Z$ than for the corresponding elements of the within-site temporal variability covariance matrix $\Sigma$, again supporting the argument that among-site variability is more important than within-site temporal variability.

References

Table A1: Reef features. For each named reef, surveys were done at either one site, or at two sites 20 m to 100 m apart. Fished reefs include community management areas with reduced harvesting intensity, and unfished reefs include those recently designated as reserves. Mean coral cover is the arithmetic mean of observed coral cover over all transects and time points.
